The authors would like to thank the anonymous reviewers for their valuable comments that have enabled the improvement of manuscript's quality. The authors would also like to acknowledge that the work presented in this paper has been partially funded by the European Union through the "Linked2Media - An Open Linked Data Platform for Semantically-Interconnecting Online, Social Media Leveraging Corporate Brand and Market Sector Reputation Analysis, FP7-SME-2011 No 286714" project.
Biographical Details:

Evangelos Kalampokis is a PhD student at the Information Systems Laboratory at the University of Macedonia, Greece. He is also a research assistant with the Information Technologies Institute of the Centre for Research & Technology - Hellas (CERTH/ITI) in Thessaloniki, Greece, while from October 2010 until November 2011 he was a research intern at the Digital Enterprise Research Institute (DERI) of the National University of Ireland, Galway (NUIG). His main research interests include Open and Linked Data, Social Media, eGovernment and Data Mining.

Efthimios Tambouris is an Assistant Professor of Information Systems at the Technology Management Department at the University of Macedonia, Thessaloniki, Greece. Before that, he served as a Researcher Grade D at the research center CERTH/ITI and at research center NCSR "Demokritos". He was also founder and manager of the eGovernment Unit at Archetypon SA, an international IT company. He holds a Diploma in Electrical Engineering from the National Technical University of Athens, Greece, and an MSc and PhD from Brunel University, UK. During the past years he has initiated and managed several research projects (e.g., IST EURO-CITI, IST eGOV, eContent eMate). He has also participated in numerous research projects (FP6/IST, e.g., OneStopGov, DEMO-net, FP5/IST, TAP, ACTS, ESPRIT, SPRITE-S2, etc.). service contracts (e.g. MODINIS Interoperability Study, European eParticipation Study) and standardisation activities (CEN/ISSS project on eGovernment metadata, CEN/ISSS eGovernment Focus Group). He has more than 120 publications in eGovernment, eParticipation, eLearning and eHealth.

Konstantinos Tarabanis is a Professor at the Department of Business Administration of the University of Macedonia, Greece, and the Director of the Information Systems Laboratory at the same university. He received an Engineering Diploma in Mechanical Engineering from the National Technical University of Athens (1983), an MS in both Mechanical Engineering and Computer Science (1984 and 1988, respectively), and a PhD in Computer Science (1991), at Columbia University, New York, NY. He was a research staff member at the IBM T.J. Watson Research Centre, 1991–1994, and was employed by the IBM Corporation as a whole during 1984–1994. In recognition of his research, he was the recipient of the Anton Philips Best Paper Award at the 1991 IEEE International Conference on Robotics and Automation. He has about 200 research publications in the areas of software modeling and development for the domains of eGovernment, eBusiness, eLearning, eManufacturing etc.

Structured Abstract:

Purpose
The purpose of this article is to consolidate existing knowledge and provide a deeper understanding of the use of Social Media (SM) data for predictions in various areas, such as disease outbreaks, product sales, stock market volatility, and elections outcome predictions.

Design/methodology/approach
The scientific literature was systematically reviewed to identify relevant empirical studies. These studies were analyzed and synthesized in the form of a proposed conceptual framework, which was thereafter applied to further analyze this literature, hence gaining new insights into the field.

Findings
The proposed framework reveals that all relevant studies can be decomposed into a small number of steps, and different approaches can be followed in each step. The application of the framework resulted in interesting findings. For example, most studies support SM predictive power, however more than one-third of these studies infer predictive power without employing predictive analytics. In addition, analysis suggests that there is a clear need for more advanced sentiment analysis methods as well as methods for identifying search terms for collection and filtering of raw SM data.

Value
The proposed framework enables researchers to classify and evaluate existing studies, to design scientifically rigorous new studies, and to identify the field’s weaknesses, hence proposing future research directions.

Keywords: Social Networks; World Wide Web; Data Analysis; Open data.

Article Classification: Research paper

Title: Understanding the Predictive Power of Social Media

Purpose: The purpose of this article is to consolidate existing knowledge and provide a deeper understanding of the use of Social Media (SM) data for predictions in various areas, such as disease outbreaks, product sales, stock market volatility, and elections outcome predictions.

Design/methodology/approach: The scientific literature was systematically reviewed to identify relevant empirical studies. These studies were analyzed and synthesized in the form of a proposed conceptual framework, which was thereafter applied to further analyze this literature, hence gaining new insights into the field.

Findings: The proposed framework reveals that all relevant studies can be decomposed into a small number of steps, and different approaches can be followed in each step. The application of the framework resulted in interesting findings. For example, most studies support SM predictive power, however more than one-third of these studies infer predictive power without employing predictive analytics. In addition, analysis suggests that there is a clear need for more advanced sentiment analysis methods as well as methods for identifying search terms for collection and filtering of raw SM data.

Value: The proposed framework enables researchers to classify and evaluate existing studies, to design scientifically rigorous new studies, and to identify the field’s weaknesses, hence proposing future research directions.

Keywords: Social Networks; World Wide Web; Data Analysis; Open data.
1. Introduction

In the past years, the use of Social Media (SM) has dramatically increased with millions of users creating massive amounts of data every day. As of September 2012, the online social networking application Facebook reached one billion monthly active users, while the microblogging service Twitter reported more than 140 million active users. SM data is typically in the form of textual content (e.g. in blogs, reviews and status updates), rating scores in Likert scales or stars (e.g. review ratings), like or dislike indications (e.g. reviews helpful votes and Facebook’s like or Google’s ‘+1’ buttons), Web search queries (e.g. Google trends), tags and profile information (e.g. social network graphs).

SM data incorporates personal opinions, thoughts and behaviours making it a vital component of the Web and a fertile ground for a variety of business and research endeavours. In this context, the predictive power of SM has been recently explored. For instance, empirical studies have analyzed the Yahoo! Finance message board to predict stock market volatility (Antweiler and Frank, 2004), weblog content to predict movies success (Mishne and Glance, 2006), Google search queries to track influenza-like illnesses (Ginsberg et al., 2009), Amazon reviews to predict product sales (Ghose and Ipeirotis, 2011) and Twitter posts (aka tweets) to infer levels of rainfall (Lampos and Cristianini, 2012).

These research efforts require cross-disciplinary skills as they involve both the transformation of noisy raw SM data into high quality data suitable for statistical analysis as well as the employment of predictive analytics, which comprise ‘predictive models designed for predicting new/future observations or scenarios as well as methods for evaluating the predictive power of a model’ (Shmueli and Koppius, 2011: 555). In this setting, a number of researchers have recently challenged...
the methods employed and the results reported by empirical studies in the area. For instance, Jungherr et al. (2012) repeated the study conducted by Tumasjan et al. (2010) and reported controversial results. In addition, Gayo-Avello (2011) and Metaxas et al. (2011) conducted a number of experiments and criticized generalizations regarding the predictive power of SM.

This article aims at consolidating the knowledge created by empirical studies in recent years that exploit SM for predictions, thus enabling an in-depth understanding of SM predictive power. More specific objectives are: (a) to identify steps that characterize all relevant studies as well as approaches that can be followed in each step, and (b) to understand how different steps and approaches are related to SM predictive power.

We anticipate that the proposed framework will enable researchers to classify and evaluate existing studies, to design scientifically rigorous new studies, and to identify the field’s weaknesses hence proposing future research directions.

The rest of the paper is structured as follows. Section 2 presents the research approach taken, while section 3 describes the proposed framework in detail. Section 4 presents the results of employing the framework to further analyze this literature, hence providing interesting results. Finally, section 5 draws conclusions.

2. Research Approach

In order to achieve the objectives of the paper we capitalize on the method proposed by Webster and Watson (2002) for conducting systematic literature reviews in the field of information systems. Initially, we performed a systematic search in order to accumulate a relatively complete body of relevant scientific literature. Towards this end, we started with Google Scholar using the key words predict OR forecast AND social media and we collected an initial pool of articles. Thereafter, we went
backward by reviewing citations in the identified articles and forward by using Google Scholar’s functionality to identify articles citing the previously identified articles. We thereafter studied and filtered these initially identified articles in order to come up with the final set that was included in our research. For this purpose, we used the following inclusion and exclusion criteria:

- We excluded qualitative or purely theoretical articles (e.g. Louis and Zorlu, 2012).

- We included only studies aiming at making predictions. As a result, we have excluded empirical studies that aim at studying the relationship between SM data and phenomena outcome following an explanatory approach (e.g. Corley et al., 2010; Chen et al., 2011; Chevalier and Mayzlin, 2006; Chunara et al., 2012; Duan et al., 2008; Morales-Arroyo and Pandey, 2010; Reinstein and Snyder, 2005; Ye et al., 2006).

- We included only studies that attempt to predict real world outcomes. Thus, we excluded studies that predict online features such as tie strength (Gilbert and Karahalios, 2009), volume of comments on online news (Tsagkias et al., 2010) or movie rating on IMDB (Oghina et al., 2012).

This approach resulted in a set of 52 articles. For the sake of clarity, the list of these articles is presented at the end of this paper in the Literature Review References section.

In order to synthesize the accumulated knowledge we performed a concept-centric analysis. The main steps and most important aspects composing the whole prediction analysis process were extracted and combined in a conceptual SM data analysis framework for predictions that structures and depicts the area. Finally, the framework
3. The Social Media Data Analysis Framework

The proposed framework comprises two discrete phases, namely the *Data Conditioning Phase* and the *Predictive Analysis Phase*. The former refers to the transformation of noisy raw Social Media (SM) data into high quality data that is structured based on some *predictor variables*. The latter phase refers to the creation and evaluation of a *predictive model* that enables estimating outcome from a *new set of observations*.

Each of these phases can be further divided into a sequence of stages and each stage into a number of steps. Finally, different approaches can be followed in each step. Figure 1 presents our framework with the two phases, the respective stages along with their steps.

| Evaluation of the Predictive Performance | ✓ Selection of the evaluation method  
✓ Specification of the prediction baseline |
The main purpose of the Data Conditioning phase is the transformation of noisy raw SM data into high quality data that will enable the computation of predictor variables. In order to define data quality we adopt and adapt a model proposed by Strong et al. (1997). In particular, we employ three data quality dimensions from Strong’s model that we consider important in the SM data analysis realm, namely objectivity, completeness and amount of data.

*Data objectivity* is related to the accuracy of data production or the accuracy of the interpretation process, and specifies whether data is what it claims to be and measures what is supposed to measure. For instance, the data produced by interpreting text’s sentiment could be of questionable objectivity in the case of non-rigorous sentiment analysis. The same holds when irrelevant data is interpreted as relevant. *Data completeness* deals with missing values from a data analysis perspective. It specifies whether or not collected data cover all aspects of a phenomenon in terms of e.g. entities characterizing it and/or predictor variables. Finally, *amount of data* (or sufficiency) specifies whether or not collected data is sufficient for predictive analysis.

The stages included in this phase along with the steps in each stage are described below.

### 3.1.1 Stage 1.1: Collection and Filtering of Raw Data

This stage deals with both raw SM data collection from various sources and filtering of data in order to determine those relevant. After its completion, the final data set that will be further analyzed during the next stage is produced. In order to determine the relevant raw data, the *when, where, who* and *what* questions should be answered. For example, it can be inferred that a tweet mentioning the Conservative Party one
A tweet posted by David Cameron in the same period. The information used to
determine relevance is extracted from the actual SM data or their metadata.

The effort required for this stage depends on both the SM and the application area.
For example, data filtering in Twitter is challenging because of its noisy nature, while
in Amazon it is straightforward as the reviews are aggregated in the product’s Web
page. Detailed steps that are involved in this stage are described below.

Determination of time window
The time window is related to the when question as it specifies the duration of the
collection activity as well as its relation to the characteristic period of the
phenomenon. The characteristic period for product sales could be related to the new-
product lifecycle (Liu et al., 2010), while for a disease outbreak to duration of
pandemic stages (Ritterman et al., 2009). Clearly, the time window affects both the
completeness and the sufficiency of the data.

Identification of location
The identification of location characterizing data is related to the where question. It is
crucial in some phenomena (e.g. determination of natural phenomena occurrence) and
thus accurate extraction of location is very important. The location characterizing SM
data can be extracted from metadata (e.g. Lampos and Cristianini, 2012; Achrekar et
al., 2011) or inferred from actual data.

Identification of user profile characteristics
The information related to the online profile of a user answers the who question. In a
number of empirical studies (e.g. Forman et al., 2008; Skoric et al., 2012) it is
suggested that this information is very important. For instance, Achrekar et al. (2011)
filter tweets from the same user within a certain syndrome elapsed time in order to

http://www.emeraldinsight.com/journals.htm?issn=1066-2243&volume=23&issue=5&articleid=17095171
Selection of search terms

The search terms selection step deals with the *what* question. In complex phenomena the identification of both the complete and correct set of search terms can be challenging. For example, Da et al. (2011) measured the search volume for 3,606 stocks through Google trends based on both “stock ticker” and “company name” and they, interestingly, identified that their correlation was only 9%. The inadequate completion of this task could result in poor quality data regarding its completeness and objectivity.

The different approaches for this step can fall into two broad categories: (a) *manual approaches* where researchers set search terms (e.g. Polgreen et al., 2008) and (b) *dynamic approaches* where search terms are derived through a computational process (e.g. Ginsberg et al., 2009). We should note that we consider the use of Google Trends’ as a dynamic selection approach since the resulting categories are determined based on Google’s natural language classification engine.

3.1.2 Stage 1.2: Computation of Predictor Variables

This stage deals with analysis of the raw data resulting from the previous stage in order to compute the values of predictor variables. In this stage, only variables related to SM are considered despite the fact that more variables (e.g. product price) can be finally employed in the predictive analysis stage. The steps composing this stage are the following:

Selection of predictor variables

Although a number of different variables have been used in the literature, we classify them into the following categories:
Volume-related variables: these measure the amount of SM data in the form of number of tweets, number of reviews, number of queries etc.

Sentiment-related variables: these measure the sentiment expressed through the data. The sentiment has been measured in the literature with the bullishness index (Oh and Sheng, 2011), review valence (Forman et al., 2008), review rating (Ghose and Ipeirotis, 2011), etc.

Profile characteristics of online users such as Facebook friends (Franch, 2012), number of followers of users that posted a tweet (Rui and Whinston, 2011), total posts (Oh and Sheng, 2011), the location of the reviewer (Forman et al., 2008) and in-degree (Livne et al., 2011).

The proper selection of the variables that are employed in the analysis can influence the completeness of the data.

Measurement of predictor variables

The majority of variables are usually measured at successive time instants separated by uniform time intervals and are thus expressed as time series. The time intervals that have been used in the literature vary from hours to months. However, in some cases variables are measured just once hence resulting in one value per variable (e.g. Tumasjan et al., 2010).

Careful selection of measurement time intervals allows predictor variables to be comparable to the actual outcome. For instance, Forman et al. (2008) aggregated data by month because the evaluation data of the outcome was formed in monthly reports. However, in some cases the measurement of variables follows different time intervals than the actual outcome data (e.g. Tumasjan et al., 2010).

Computation of predictor variables
Although the computation of volume-related variables is straightforward and provides accurate results, the computation of sentiment expressed in text can be cumbersome and may provide poor results. Literature reveals that many research efforts have come up with poor sentiment analysis results (e.g. Gayo-Avello, 2011; Metaxas et al., 2011), mainly because of the informal and noisy nature of SM that creates problems to widely used NLP tools. The poor performance of sentiment analysis is a major source of weakness in the quality of data objectivity as the interpreted sentiment is different than that actually expressed.

In general the approaches used for sentiment computation can be categorized as follows: (a) lexicon-based, where sentiment is defined by the occurrence in the text of words included in a pre-defined lexicon (e.g. Metaxas et al., 2011; O’Connor et al., 2010) and (b) machine learning, where sentiment is computed by language model classifiers (e.g. Asur and Huberman, 2010).

3.2 Phase 2: Predictive Analysis

The aim of this phase is the creation and evaluation of a predictive model that will enable accurate prediction of phenomenon outcomes based on a new set of observations, where new can be interpreted as observations in future or observations that were not included in the original data sample.

Statisticians recognize that analyses aimed at prediction are different from those aimed at explanation (Konishi and Kitagawa, 2007). Predictive power refers to the ability of predicting new observations accurately, while explanatory power to the strength of association indicated by a statistical model. ‘A statistically significant effect or relationship does not guarantee high predictive power, because the precision or magnitude of the causal effect might not be sufficient for obtaining levels of predictive accuracy that are practically meaningful’ (Shmueli and Koppius, 2010: http://www.emeraldinsight.com/journals.htm?issn=1066-2243&volume=23&issue=5&articleid=17095171

This is a pre-print version of the following article: E. Kalampokis, E. Tambouris and K. Tarabanis (2013) Understanding the Predictive Power of Social Media. Internet Research, Vol.23, No.5, pp.544-559 http://dx.doi.org/10.1108/IntR-06-2012-0114
predictive power, empirical studies that make predictive claims often infer predictive power from explanatory power without employing predictive analytics (Shmueli and Koppius, 2010).

3.2.1 Stage 2.1: Creation of Predictive Model

In this stage the actual model is created based on statistical or data mining methods. The steps that compose this stage are described below.

Selection of predictive method

The actual model of the predictive analysis is built based on different statistical or data mining methods. The most common method in literature is linear regression but many others have been also employed such as logistic regression (Livne et al., 2011), Markov models (Gruhl et al., 2005), neural networks (Bollen et al., 2011), support vector machine (Ritterman et al., 2009) and Granger causality (Gilbert and Karahalios, 2010).

Selection and use of non-SM predictor variables

Apart from the predictor variables computed through SM data, other predictor variables are also used in the predictive model. These usually express objective facts, such as past values of phenomenon outcomes and demographics. For instance, Forman et al. (2008) studied the relation between both the average valence of a review and the percentage of reviews disclosing real name or location, and product sales on Amazon. Towards this end, they also employed product price as a control variable in order to reduce the possibility that results reflect differences in average unobserved product quality rather than aspects of the reviews per se. In addition, Rui and Whinston (2011) employed non-SM predictor variables such as budget of a movie or the fact that a movie is a sequel in order to enhance the accuracy of the

http://www.emeraldinsight.com/journals.htm?issn=1066-2243&volume=23&issue=5&articleid=17095171
model and Da et al. (2011) employed the number of news data from the Wall Street Journal in order to predict stock prices.

**Identification of data for evaluation of prediction**

The data referred to here represent the actual phenomenon outcome. This data is taken from official sources such as governmental documents and Web sites (e.g. Lampos and Cristianini, 2012; Sakaki et al., 2010; Ettredge et al., 2005), other trustworthy Web sites (e.g. Bollen et al., 2011), international organizations (e.g. O'Connor et al., 2010), etc. The accuracy and timely collection of this data is important for the creation of the predictive model.

**3.2.2 Stage 2.2: Evaluation of the Predictive Performance**

In this stage prediction accuracy is evaluated against the actual outcome. The steps that comprise this stage are described below.

**Selection of the evaluation method**

The evaluation of predictive performance is very important as it provides the actual result of the study as a whole. In the literature two different approaches are mainly employed: (a) *explanatory* analytics and (b) *predictive* analytics. The former assesses the statistical significance of the model using metrics such as p-values or $R^2$ (e.g. Asur and Huberman, 2010). The latter usually obtains out-of-sample data to be used for actual evaluation based on metrics such as out-of-sample error rate and statistics such as Predicted Residual Sums of Squares (e.g. Bordino et al., 2012), Root Mean Square Error (e.g. Achrekar et al., 2011), Mean Absolute Percentage Error (e.g. Bollen et al., 2011; Liu et al., 2007) and cross-validation summaries.

In general, the criteria that specify whether a study follows a predictive evaluation method or not are the following (Shmueli and Koppius, 2010):

- Was predictive accuracy based on out-of-sample assessment?
Was predictive accuracy assessed with adequate predictive measures?

**Specification of the prediction baseline**

The baseline for prediction is an important element in the literature as it provides an extra metric for evaluating predictive power. The predictive power of an SM data based model is often judged in relation to statistical models fit with traditional data sources (e.g. Goel et al., 2010; Rui and Whinston, 2011) or past values (e.g. Bollen et al., 2011; Ritterman et al., 2009; Wu and Brynjolfsson, 2009). In addition, the results of prediction are sometimes also evaluated against prior models and approaches (e.g. Ghose and Ipeirotis, 2011).

**4. Understanding the Predictive Power of Social Media**

We now employ our framework in order to gain insight into the predictive power of Social Media (SM). We initially categorize the identified articles based on the application area studied (Table 1) and the type of SM employed (Table 2).

**Table 1 The application areas studied in the literature**

Table 3 presents classification of the literature according to the approach employed for selecting search terms, which is vital in Stage 1.1 of the framework. The table suggests that the vast majority of the studies employs manual selection methods.

http://www.emeraldinsight.com/journals.htm?issn=1066-2243&volume=23&issue=5&articleid=17095171
In Table 4 the studies that involve sentiment analysis are aggregated and categorized according to the method they have employed. Selecting such a method is important in Stage 1.2 of the proposed framework. In this table we do not include studies that express the sentiment as review ratings since its measurement is straightforward.

| Table 4 Classification of literature according to the text's sentiment analysis approach |
|---------------------------------|--------------------------------------------------|
| **Lexicon-based**               | Bollen et al. (2011); Gayo-Avello (2011); Liu et al. (2010); Metaxas et al. (2011); O’Connor et al. (2010); Zhang et al. (2011a); Zhang et al. (2012b) |
| **Machine Learning**            | Antweiler and Frank (2004); Asur and Huberman (2010); Bothos et al. (2010); Gayo-Avello (2011); Gilbert and Karahalios (2010); He et al. (2012); Krauss et al. (2008); Liu et al. (2007); Mishne and Glance (2006); Oh and Sheng (2011); Rui and Whinston (2011) |

Based on the criteria employed by Shmueli and Koppius (2010) we also classify (Table 5) literature according to the approach used to infer SM predictive power.
Finally, Table 6 categorizes literature according to their final outcome with regard to the predictive power of SM. Some studies provide evidence for both outcomes. These are included in both categories.
By synthesizing Tables 1-6 we can further analyze the empirical studies in the literature and make some interesting observations.

**Search term selection**

Table 3 suggests that although dynamic search term selection is used in most application areas (Table 1), it only appears in studies that employ Web search and microblog data (Table 2). Furthermore, all these studies support SM predictive power (Table 6) based on predictive analytics (Table 5). In the case of manual search term selection when considering the same two SM categories, the percentage of studies that support SM predictive power falls off to fifty percent (50%). Hence, we can conclude that search term selection is of vital importance in microblog and Web search data, and thus these SM categories call for sophisticated search terms selection methods. For instance, Lampos and Cristianini (2012) successfully estimated daily rainfall rates for five UK cities by identifying relevant tweets through the application of Bolasso (i.e. the bootstrapped version of Least Absolute Shrinkage and Selection Operator) for search term selection.

**Sentiment analysis**

Table 4 suggests that the majority of studies that employ sentiment analysis investigate stock market and movies (Table 1). Although sentiment seems to be important in application areas such as elections, product sales and macroeconomics,
only six (6) out of twenty four (24) studies include a sentiment-related independent variable. Disease outbreaks and natural phenomena related studies do not employ sentiment, as one might have expected. Interestingly however, forty per cent (40%) of studies that have used sentiment-related variables challenge SM predictive power. This number increases to sixty five percent (65%) in the case of lexicon-based approaches, while it falls off to twenty percent (20%) in those of machine learning. Hence, it seems that sentiment analysis in SM requires innovative approaches that could address the noisy and informal nature of SM.

Evaluation method

In general, half of the studies do not use predictive analytics to draw conclusions on the predictive performance of SM. These studies span equally across all SM categories (Table 2). With regard to application areas (Table 1), the vast majority of election-related cases do not follow a predictive analytics evaluation, while most studies related to macroeconomic indices, natural phenomena and product sales application areas evaluate predictive power based on prediction analytics. The evaluation of a predictive model with out-of-sample data is sometimes challenging. For instance, in the case of election-related studies the outcome is produced once every four or five years. In order to overcome this limitation Franch (2012) used poll data.

Tables 5 and 6 suggest that ten (10) out of fourteen (14) studies that challenge SM predictive power have used explanatory evaluation methods. This fact does not imply that these studies do not contribute to the understanding of SM predictive power as lack of a statistically significant relationship indicates low predictive power. In addition, fourteen (14) out of forty (40) studies that support SM predictive power infer predictive power without employing predictive analytics. Here we should also
note that if these studies had used predictive evaluation methods, they could have presented high predictive power. However, based on the reported results we cannot assess their predictive power because a statistically significant relationship does not always ensure high predictive power. For example, ‘low predictive power can result from over-fitting, where an empirical model fits the training data so well that it underperforms in predicting new data’ (Breiman, 2001: 204).

**Application areas**

The application area of a study seems to be related to the accuracy of the prediction that the study presents. Some application areas, such as disease outbreak and natural phenomena, do not involve the expression of any kind of opinion or sentiment. The signal that the researcher has to decode in these cases has to do with the occurrence or not of the event. As a result, these studies are expected to provide more accurate predictions than studies requiring extracting opinions or sentiment out of raw data. Moreover, some application areas, such as elections or macroeconomics, can be characterized as complex because they involve multiple and interrelated real-world entities such as political parties and politicians or complex concepts such as consumer confidence or inflation rate. The identification of the complete set of relevant raw SM data in these cases is challenging and hence call for sophisticated methods.

This becomes evident if we elaborate on two of the identified applications areas, namely elections and disease outbreak. The former involves opinion expression and is characterized by multiple and interrelated real-world entities (i.e. political parties, candidates, election constituencies), while the latter does not require opinion extraction. Table 1 suggests that all eleven (11) election-related studies selected their search terms manually (Table 3) and only three of them employed sentiment-related variables (Table 4). These facts could provide an explanation of the unfavourable and
controversial results reported in the literature regarding predictability of election results through SM. In addition, half of the disease outbreak related studies employed sophisticated search unit selection approaches, eighty percent (80%) used predictive analytics evaluation and ninety percent (90%) supported SM predictive power.

5. Conclusions

Social media (SM) are a vital component of the contemporary Web as they enable the production of data that reflects personal opinions, thoughts and behaviour. Since the emergence of blogs and forums, several research efforts have explored the potential of SM data for predictions of outcomes such as disease outbreaks, product sales, stock market volatility, and elections. As the field is immature, some studies produce controversial results and doubtful outcomes.

In this article, we aim at consolidating knowledge created in the past eight years by empirical studies that aim at predicting real world outcomes through SM, thus enabling an in-depth understanding of SM predictive power. Towards this end, we identify and synthesize the literature and we create a SM data analysis conceptual framework for predictions. Using this framework we further analyze the literature and classify studies according to the approaches they follow and the results they report.

The proposed framework suggests that all relevant studies can be decomposed into a small number of steps and that different choices can be made in each step. The application of the framework enabled us to make some interesting observations. The majority of the empirical studies support SM predictive power, however more than one-third of these studies infer predictive power without employing predictive analytics. Sophisticated search term selection is crucial in Web search and microblog data. In addition, the use of sentiment-related variables resulted often in controversial outcomes proving that SM data call for sophisticated sentiment analysis approaches.
We anticipate that both the framework and analysis results will enable researchers to design scientifically rigorous new studies and to more easily identify the field’s weaknesses, hence proposing new future research directions.
